#### Abstract

The report presents a comparison of different assessment methods and the state of the plaice stock (Pleuronectes platessa) in Icelandic waters. Four alternative assessment methods are used: age-based ADAPT, length-based ADAPT, age-disaggregated dynamic and the surplus production model. Most of the data used in this study are from the Marine Research Institutes (MRI). Age-disaggregated observations are used as input data for the age-based ADAPT method and age-disaggregated dynamic production model. For the length-based ADAPT method, the length frequency data are used as the input source and converted into age using the slice method and then used as input data for the lengthbased ADAPT model and catch by year, biomass indices and CPUE for the surplus production model. The reference points model with R-S relationship (B-H) is used to estimate the stock state. The different models give similar trends in fishing mortality rates over the period studied (1987-2004) and similar F in the final year ( $0.16-0.25$ ). The stock biomass declined from approximately $50,000 \mathrm{t}$ in 1987 to around $22,000 \mathrm{t}$ in 2004. Mean recruitment from 1987-2004 is around 30 million and declining. The long term predicted yield for the next 15 years is about $7,000-9,000 \mathrm{t}$ and the short term predicted yield for the next three years is about $4,000-5,000 \mathrm{t}$. Results from the surplus production model show that the stock biomass declined from approximately $80,000-90,000 \mathrm{t}$ in 1905 to around $14,000 \mathrm{t}$ in 2000 and then increased to about $23,000 \mathrm{t}$ in 2004. The estimates of reference points show that the current fishing mortality has declined to historically low levels. The recruitment between 1987 and 2004 was variable and included a few high values. Since 2000, recruitment has decreased and has been less than average. The SSB estimated in 2004 of $22,000 \mathrm{t}$ is above the Bpa of $15,389 \mathrm{t}$. Short term predictions suggest that SSB will increase to around $26,000 \mathrm{t}$ by 2007 at current levels of fishing mortality. The recommended fishing mortality from long term predictions is less than 0.26 for the period 2005-2015 to increase the stock and catch to around $40,000 \mathrm{t}$ and $8,000 \mathrm{t}$.

## 1 INTRODUCTION

Plaice, Pleuronectes platessa (Linnaeus, 1758) is a medium to large sized flatfish. Plaice is common all around Iceland from 0 to 200 m , on sandy or muddy bottoms. It can also tolerate fresh water for some time. In European waters it is found from the White Sea and the Barents Sea in the north down to the western part of the Mediterranean Sea in the south. Plaice undertakes large scale feeding and spawning migrations in the waters around Iceland (Jónsson 1992). The plaice's diet mainly consists of various benthic invertebrates, dominated by polychaetes and bivalves, but also sand eels to some extent (Pálsson 1983).

Plaice is a commercially important flatfish. Apart from plaice there are a number of other important flatfish stocks in Icelandic waters, including Greenland halibut, dab, long rough dab, lemon sole, witch and halibut. All these stocks are fully utilised by the Icelandic fleet and TACs have been established for them in recent years. Data on the plaice fishery in Iceland are available from the year 1913 for Iceland and from 1905 for other nations fishing in Icelandic waters (Figure 1). Because of its high value, it has sustained high catches in Icelandic waters. The catch was about $10,000 \mathrm{t} / \mathrm{y}$ and $5,000 \mathrm{t} / \mathrm{y}$ in the $1960 \mathrm{~s}-70 \mathrm{~s}$, while from 1984-1997 the catches were 10,000 to $14,000 \mathrm{t} / \mathrm{y}$, higher than ever before. Recent catches have been about 5,700 to $7,000 \mathrm{t} / \mathrm{y}$ (Table 1). Most of the catch is taken by Danish seine, but a considerable share is taken by bottom trawls. Most of the catch consists of 5-6 year old fish, $35-40 \mathrm{~cm}$ long. Fishing effort is considered too great and the abundance index for the fishable stock shows a marked decline in recent years (Table 4).

In 1986 the Marine Research Institute (MRI) initiated a sampling programme from landings and from that year onwards samples have been taken regularly from landings. Furthermore all vessels participating in the plaice fishery have been obliged since 1987 to fill out detailed logbooks for the MRI. Plaice catches have been registered, sexed and length measured in the Icelandic spring ground-fish survey (IGFS) since 1985. In 1995 the sampling scheme of the Nephrops survey off the south coast was reconstructed to include plaice.

Figure 1: Plaice catch from Icelandic waters.

Since 1994 the MRI has given advice on the exploitation of plaice based on CPUE from Danish seine fleets, TAC for the fishing year 2004/2005 is $5,000 \mathrm{t}$ based on CPUE, but the Marine Research Institute (MRI) recommended that fishing should be limited to $4,000 \mathrm{t}$ in the period (Marine Research Institute 2004/2005).

Plaice is the most studied of Icelandic flatfishes. Studies on population dynamics have however been hampered by the different fishing gears used and lack of a continuity in the studies (Valtysson 1998). Now this has been supplemented by increased sampling effort from ports of landing all around the country. Annual trawl surveys since 1985, covering most of the fishing grounds in Iceland, give valuable information on the trend in stock size of all the flatfish species.

In a discussion of model selection, Hilborn and Walters (1992) suggest adopting a pragmatic approach. Assuming the data are available, they imply that one should apply both surplusproduction and age-structured methods, which, because they are fundamentally different, will provide a test of relative performance. The main objective of this study is to assess the plaice stock with various assessment methods to evaluate the effect of different assessment methods on the stock estimates, to obtain overall indication of stock trends and exploitation since 1987, Biological reference points (BRP) as well as short term and long term predictions. Four assessing methods are used: 1) ADAPT/VPA/Cohort analysis, a standard method of assessment using catches in number by age by year combined with tuning indices to obtain stock size in number at age. 2) Length-based ADAPT-VPA, using length frequency data as the input source. This method is performed in two steps. The first step is to disaggregate the age from the length distribution data using the least squares method, corresponding to a simplified version of the maximum likelihood method (slice). The second step is to use the VPA-ADAPT method to estimate stock size with the data obtained. 3) Age-disaggregated Dynamic Production Model (ADPM) using catches in number by age by year, CPUE and survey indices to fit the dynamics of the stock with internal age groups including various error assumptions. 4) Surplus production model using biomass indices from survey and CPUE to fit the dynamics of the stock.

## 2 MATERIAL AND METHODS

### 2.1 Available data and biological parameters

### 2.1.1 Available data

Most of the data used in this study are from the Marine Research Institutes (MRI) and unpublished.

The sets of data used include the following:
a. Total nominal annual catches in tons of plaice from Icelandic waters 1905-2004. Data from the annual report on the State of Marine Stocks in Icelandic Waters 2004/2005 (Table 1).
b. Catch in number by age by year (Table 2), mean length and weight at age from 1987-2004 (Tables 6 and 7), length along with length distributions from 1987-2005 (Table 8), the lengthweight relationship data from 1994-2005 (MRI Databases) and maturity at age (Table 9) from 2002-2004.
c. CPUE indices: CPUE indices (Table 3) based on Icelandic Danish seine fleets log-books from 1991-2004. This is the mean catch when more than $10 \%$ of the total catch was plaice.
d. Icelandic ground fish survey (IGFS) indices from 1985 to 2005 (Tables 4 and 5). These are total abundance and recruitment indices of plaice based on data from the IGFS. They were estimated with the Cochran method by depth strata. The IGFS is designed for cod and therefore the sampling is not optimal for plaice.

### 2.1.2 Biological parameters

- Parameters for the von Bertalanffy (Bertalanffy 1938) growth equation. The growth parameters were estimated from the database on length at age (MRI Database) by finding the best fit to the observed length at age with the maximum likelihood method (Malcolm 2001).

$$
\begin{aligned}
& \boldsymbol{L}_{a}=\boldsymbol{L}_{\infty}\left(\mathbf{1}-e^{-k\left(a-t_{0}\right)}\right)+\boldsymbol{\varepsilon} \\
& \hat{\sigma}^{2}=\frac{\sum_{i=1}^{n}\left(L_{a i}-b \hat{L}_{a i}\right)^{2}}{n} \\
& L L=-\frac{n}{2}[\operatorname{Ln}(2 \pi)+2 \operatorname{Ln}(\hat{\sigma})+1] \\
& \operatorname{MIN}(-L L) \\
& C V=\sqrt{\frac{L L}{n}}
\end{aligned}
$$

where $L_{a}$ is length at age a, $L_{\infty}$ is the theoretical maximum length the species can reach, k
is growth coefficient that measures the rate at which the $L_{\infty}$ is reached, a is the age and $\mathrm{t}_{0}$ is theoretical age at zero length, $L_{a i}$ is the observation length, $\hat{L}_{a i}$ is estimated length and $L L$ is the value of Maximum Likelihood, $n$ is number of data points.

- Parameters for the length-weight relationship. The growth-weight relationship parameters were also estimated from the MRI database on length-weight, by finding the best fit to the observed weight with the maximum likelihood method.

$$
\begin{aligned}
& W=\alpha L^{\beta}+\varepsilon \\
& \hat{\sigma^{2}}=\frac{\sum_{i=1}^{n}(W-b \hat{W})^{2}}{n} \\
& L L=-\frac{n}{2}[\operatorname{Ln}(2 \pi)+2 \operatorname{Ln}(\hat{\sigma})+1] \\
& \operatorname{MIN}(-L L) \\
& C V=\sqrt{\frac{L L}{n}}
\end{aligned}
$$

where $\alpha$ and $\beta$ are constants.

- Maturity rate at age estimation. The theoretical ogive of maturity at age is estimated from the equation below (Pearl and Reed 1922) with the data from MRI (Table 9).
$\hat{\mathrm{P}}_{\mathrm{i}}=\frac{1}{1+e^{a^{*}\left(t-P_{50}\right)}}$
$S S E=\sum_{i=1}^{n}\left(P_{i}-\hat{P}_{i}\right)^{2}$
where $\hat{p}_{i}$ is the proportion of mature individuals at age group i , a and $p_{50}$ are the parameters of the equation which will then be estimated by the least-squared method to give the best fit of expected-to-observed, and $p_{i}$ is the proportion of mature individuals at age group i from the observed.
- Natural mortality rate (M): Preliminary studies on plaice in Faxaflói Bay (Sigurdsson 1962) in the late 1950s estimated a total annual mortality of $19 \%$. This should be close to the natural mortality since catches were very low during this period. No further studies have been conducted on the natural mortality of plaice in Icelandic fishing grounds. The value used by the MRI for the witch flounder and the plaice is 0.15 and here we also use this value.

### 2.2 Stock assessment methods

### 2.2.1 Age-based ADAPT

ADAPT-VPA (Deriso1985, Gavaris 1988) is a well known method of assessment using catches in numbers at age (Table 2) combined with tuning indices to obtain stock size in numbers at age. In this method, it is assumed that fishing takes place at around the middle of the year and that natural mortality will only affect the stock before and after the fishing season. Natural mortality is assumed to be constant with regard to age and time and is denoted by M. This method uses fishing mortality rates in the last year as the starting point of the calculation instead of stock size of the last year. The fishing mortality rates of the last year are then determined by a "tuning" method, in this case based on ADAPT. The fishing mortality rate of the oldest group is taken as an average of fishing mortality rates for some penultimate younger age groups of the oldest during the same year.

The stock size in numbers in the last year is calculated through the inversion of the catch equation:

$$
\begin{equation*}
N_{a y}=\frac{C_{a y}}{\left(F_{a y} / Z_{a y}\right) *\left(1-e^{-Z_{a y}}\right)} \tag{1}
\end{equation*}
$$

Where |  | $N_{a y}$ |
| ---: | :--- |
|  | $N_{a+1, y+1}$ |
| $Z_{a y}$ |  |
|  | $F_{a y}$ |
|  | $C_{a y}$ |

is the size of the age group a in year $y$
is the size of the group a in the next year to the year y
$Z_{a y} \quad$ is the total mortality rate for the age group a in year y
$C_{a y} \quad$ is the total catch in number of the age group a in year y

For a given age group $a$ having the size $\mathrm{N}_{\mathrm{ay}}$ at the beginning of year $y$, provided no fishing takes place in the first six months, the size of the year-class at the middle of the year will be (Pope 1982):

$$
N_{a y} * e^{-M / 2}
$$

If the entire catch is taken at this point of time, the size of the year-class is reduced to:

$$
N_{a y} * e^{-M / 2}-C_{a y}
$$

Then the year-class decreases due to natural mortality, so the survival of the year-class at the end of the year is:

$$
\begin{equation*}
N_{a+1, y+1}=\left(N_{a y} * e^{-M / 2}-C_{a y}\right) * e^{-M / 2} \tag{2}
\end{equation*}
$$

For back calculation of the stock size, this equation can be reversed:

$$
\begin{equation*}
N_{a y}=\left(N_{a+1, y+1} * e^{M / 2}+C_{a y}\right) * e^{M / 2} \tag{3}
\end{equation*}
$$

Since the stock size of the last year is already known from equation (1), the second to last year can be back calculated using equation (3).

Once the stock size $\mathrm{N}_{\text {ay }}$ of the last year and the second to last year is known, the fishing effort $\mathrm{F}_{\text {ay }}$ of the second to last year can be computed, using the basic equation:

$$
N_{a+1, y+1}=N_{a y} * e^{-Z_{a y}}
$$

The natural logarithm is taken on both sides to get the estimate of $\mathrm{Z}_{\mathrm{ay}}$ :

$$
Z_{a y}=\ln \left(N_{a y}\right)-\ln \left(N_{a+1, y+1}\right)
$$

The total mortality (Zay) is the sum of fishing mortality $\left(\mathrm{F}_{\text {ay }}\right)$ and natural mortality $(\mathrm{M})$ :

$$
\begin{equation*}
F_{a y}=Z_{a y}-M=\ln \left(N_{a y} / N_{a+1, y+1}\right)-M \tag{4}
\end{equation*}
$$

In principle, the fishing mortality rates of the oldest age groups can be estimated, but these are always prone to large errors. Therefore, the fishing mortality of the oldest age is set as the average of some younger age groups.

For the last year the estimation is reduced to estimating a single fishing mortality. It can be estimated on the basis of the patterns of the previous years. In some cases the selection patterns are not accurately determined and not in accordance with what is expected from the gear used. Therefore, the simplification is made that the selection pattern in the latest year is fixed equal to the average selection in some years prior to the last one. In this project, the average selection pattern is taken as the short term average selection pattern of the three years prior to the last one (1999-2001).

It is now possible to use exactly the same method to estimate the stock size of the third last year and then continue to back calculate stock sizes and mortality rates completing the stock size.

Survey and commercial fisheries information on biomass and CPUE are used as indices of abundance by year I, U, R indices (Tables 3a, 3b, 3c) which are assumed to be related to stock abundance as follows:
$\hat{I}_{y}=q_{1} * B_{y} \quad(\mathrm{y}=1987-2004)$
$\hat{U}_{y}=q_{2} * B_{y} \quad(\mathrm{y}=1991-2004)$
$\hat{R}_{y}=q 3 * N_{2, y} \quad(\mathrm{y}=1987-2004)$
$B_{y}=\sum_{a=2}^{20}\left(W_{a} * N_{a y}\right)$
where $q_{1}, q_{2}$ and $q_{3}$ are constants.

If VPA is employed with the correct input, it should provide a sound stock estimate. This estimate can in turn be used to compare indices from survey and CPUE data and therefore it is feasible to verify whether a given stock estimate is in accordance with a time series of survey and CPUE data.

One possible way to conduct such a comparison is through stating that for a given terminal fishing mortality coefficient in the last year and a given relationship with indices, the deviation (sum squared errors, SSE) in the forecast concerning indices is given by:

$$
\begin{array}{ll}
S S E I=\sum_{y=1}^{18}\left(\ln \left(I_{y}\right)-\ln \left(\hat{I}_{y}\right)\right)^{2} & (\mathrm{y}=1987-2004) \\
S S E U=\sum_{y=1}^{14}\left(\ln \left(U_{y}\right)-\ln \left(\hat{U}_{y}\right)\right)^{2} & (\mathrm{y}=1991-2004) \\
S S E R=\sum_{y=1}^{18}\left(\ln \left(R_{y}\right)-\ln \left(\hat{R}_{y}\right)\right)^{2} \\
S S E=w 1^{*} S S E I+w 2 * S S E U+w_{3}^{*} S S E R \tag{5}
\end{array}
$$

where $w 1, w 2$ and $w 3$ are weight for SSE.
Then $N_{a y}, B_{y}, F_{a y}, F_{y}, R_{y}$ are estimated from the Biomass and Recruitment of survey and CPUE, by finding the best fit to the observed the Biomass of survey and CPUE.

Where $B_{y}$ is the predicted Biomass in year y
$F_{y} \quad$ is the predicted fishing mortality rate in year y
$R_{y} \quad$ is the predicted recruitment in year y
The age-disaggregated catches in numbers by age by year (Table 2 ) were used for the cohort analysis, the biomass and recruitment indices from survey (Tables 3, 4,5) and CPUE from landing for the tuning process. The reference fishing mortality, F, is taken as the average fishing mortality of ages 6-12 as these age groups are dominant in the catch.

The selection pattern by age, $S_{a}$, is taken as average $S_{a}$ of the years 1999-2001 (Table 13, Figure 6). Fishing effort of the oldest group is taken as the average of the fishing mortality of the three younger ages from age 17-19. The mean weight at age by year (Table 11) and maturity at age by year (Table 9) are used for estimating the stock biomass and spawning stock biomass.

The method of least-squares was used to estimate F and stock size of the last year by minimising the sum of squares of the differences between the observed and model predicted biomass and recruitment indices and CPUE.

### 2.2.2 Length-based ADAPT

In the length-based method used in this project, length distributions are disaggregated into age distributions, using available length frequency data on landings to obtain the total catch in number at age by year.

The length-based method uses the length frequency data as its input source. It contains two steps. The first step is to disaggregate the age from the length distribution data using the slice method. The second step is to use the method VPA-ADAPT as described in section 2.2.1 to analyse the data obtained.

The length frequency data, which will be used as input for the model, are from commercial landing samples in 1987-2004 (Table 8) and then frequency data were converted into total number (Table 10) according to catch from 1987-2004 (Table 1). The conversion to age distribution from length distribution data is performed with the slice method, from which the information on the mean length at age, standard deviation, and probability of density (or proportion) at age are also estimated.

The slice method (Stefansson G. 2005) can be shown by the following equation. The density function of the Gaussian distribution with mean length $\mu$ and variance $\sigma^{2}$ is given by:
$f(x)=\frac{1}{\sqrt{2 \pi} \sigma} e^{-(x-\mu)^{2} /\left(2 \sigma^{2}\right)}$
and the cumulative distribution is:

$$
F(x)=\int_{-\infty}^{x} \phi(t) d t=\Phi\left(\frac{x-\mu}{\sigma}\right)
$$

Take a fixed age group of fish and assume that they are distributed along the length axis according to a Gaussian density, with some mean length ( $\mu_{a}$ ) and some standard deviation of length at age $\left(\sigma_{a}\right)$.For this age group, the proportion of fish within length category $l$ of width 1 is:
$\Phi\left(\frac{(l+1 / 2)-\mu_{a}}{\sigma_{a}}\right)-\Phi\left(\frac{(l-1 / 2)-\mu_{a}}{\sigma_{a}}\right)$

Since this is the probability of a fish having a length between $l-\frac{1}{2}$ and $l+\frac{1}{2}$ now, suppose the true proportion of fish in age group $a$ is $\pi_{a}$. In this case the proportion of fish in length group $l$, across all ages becomes:

$$
\begin{aligned}
& \hat{P}_{l a}=\sum_{a} \pi_{a}\left\{\Phi\left(\frac{(l+1 / 2)-\mu_{a}}{\sigma_{a}}\right)-\Phi\left(\frac{(l-1 / 2)-\mu_{a}}{\sigma_{a}}\right)\right. \\
& S S E=\sum_{a=1}^{19}\left(\ln \left(P_{l a}\right)-\ln \left(\hat{P}_{l a}\right)\right)^{2} \quad(a=\text { age 2-20 })
\end{aligned}
$$

The unknown parameters in this formula are the proportions in each age group, $\pi_{a}$, the mean length at age, $\mu_{a}$, and the standard deviations, $\sigma_{a}$.

Given data (Table 8) on the proportions at length can be compared to the theoretical proportions. A formal statistical approach would be to estimate the unknown parameters by minimising the discrepancy between the observed and theoretical values.

### 2.2.3 Age-disaggregated dynamic production model

This model attempts to draw out the overall picture of how the stock has changed from year to year since 1987. The catch in number by age by year from Icelandic waters in 1987-2004 (Table 2), Biomass, recruitment indices (number at age 2) form survey and CPUE indices from Danish seine fleets log-books 1991-2004 (Tables 3-5) will be used to fit a dynamic stock production model with internal age groups. Various error assumptions, including process error, will be included.

Assuming that in 1986 there is no fishing of the stock and a virgin value of recruitment $R_{0}\left(N_{1986,2}=R_{0}\right)$, the stock size is calculated for this year is:
$N_{a+1,1986}=N_{a, 1986} * e^{-M}$
where $R_{0}$ will be estimated.

After fishing commences in 1987, with initial series of F multipliers over years, the stock size by age by year is estimated as follows:
$N_{a+1, y+1}=N_{a y} * e^{-Z_{a y}}$

It is also assumed that there is a simple relationship between stock and recruitment (or production), expressed by the Beverton and Holt equation (Beverton and Holt 1957):
$R=\alpha^{*} B_{y} /\left(1+B_{y} / K\right)$

Where $B_{y}$ is spawning stock biomass, $\alpha$ is a constant and $K$ is the size of the spawning stock that produces half the maximum recruitment.

The parameters $\alpha, K, R_{0}, F$ will be adjusted to provide the best fit of the predicted-toobserved data. The fitting procedure used in this model is least-squares fitting (Malcolm 2001) (Shepherd 1999):
$S S E C=\ln \left(\sum_{y=1987}^{2004} \sum_{a=2}^{20}\left(C_{a y}-\hat{C}_{a y}\right)^{2}\right)$
$S S E B=\ln \left(\sum_{y=1987}^{2004}\left(B_{y}-\hat{B_{y}}\right)^{2}\right)$
$S S E U=\ln \left(\sum_{y=1991}^{2004}\left(U_{y}-\hat{U}_{y}\right)^{2}\right)$
$\operatorname{SSER}=\ln \left(\sum_{y=1987}^{2004}\left(R_{y}-\hat{R_{y}}\right)^{2}\right)$
$\operatorname{SSE}=w_{c} * \operatorname{SSEC}+w_{b} * \operatorname{SSEB}+w_{u} * \operatorname{SSEU}+w_{r} * \operatorname{SSER}$
Where $S S E$ is the total sum of squared errors, $\hat{C}_{a y}, \hat{B}_{y}, \hat{U}_{y}, \hat{R}_{y}$ are the model predicted catch in number by age by year, biomass indices, abundance indices and recruitment indices, $w_{c}, w_{b}, w_{u}, w_{r}$ respectively is the weight for the corresponding SSE.

To predict the catch in number by age by year, the following equation is used:
$\hat{\mathrm{C}}_{\mathrm{ay}}=\frac{F_{a y}}{Z_{a y}}\left(1-e^{-Z_{a y}}\right) N_{a y}$

To predict biomass indices $\hat{B}_{y}$, it is assumed that there is a relationship between stock size and biomass indices from a survey:
$\hat{B}_{y}=q_{1} * B$
where $B$ is the exploitable biomass of the stock, $B=N_{a y} * W_{a y} * S_{a y}$ $q_{1}$ is a constant and $S_{a y}$ is selection pattern by age by year.

To predict abundance indices $\hat{U}_{y}$, it is assumed that there is a relationship between stock size and CPUE indices:
$\hat{U}_{y}=q_{2} * B$
$q_{2}$ is catchability and assumed to be constant every year.

To predict the recruitment index $\hat{R}_{y}$, the following equation is used:
$\hat{R}_{y}=q_{3} * N_{2, y}$
where $N_{2, y}$ is the number of age 2 or the recruitment estimated from the stock- recruitment relationship.

### 2.2.4 A short term yield and biomass prediction for the next three years

With the given stock size estimation of the last year (2004), it is possible to compute catch projections. The outcome of the stock size estimation usually states the number of fish in the sea at the beginning of the last year for which data is available.

The stock size of the next three years is calculated using the following equation:

$$
\begin{aligned}
& N_{a y}=N_{a-1, y-1} * e^{-Z_{a-1, y-1}} \\
& B_{y}=\sum_{a=2}^{20}\left(N_{a y} * W_{a} * S_{a}\right)
\end{aligned}
$$

where $B_{y}$ is the exploitable biomass of the stock, $W_{a}$ is weight at age and $S_{a}$ is the selection pattern at age.

The natural mortality for the last year is known. The fishing mortality rate of the next three years is assumed to be equal to the fishing mortality of the last year. That means that the fishing pattern is assumed to remain the same from 2004 to 2005:

$$
F_{a y}=F_{a-1, y-1}
$$

The catch in number by age of the next three years will now be calculated using the catch equation:

$$
C_{a y}=\frac{F_{a y}}{Z_{a y}} *\left(1-e^{-Z_{a y}}\right) * N_{a y}
$$

The recruitment of the next three years is estimated by the B-H recruitment model with the biomass of the previous year.

Total yield of the next three years will be estimated by the equation:

$$
Y_{y}=\sum_{a=2}^{20}\left(C_{a y} * W_{a y}\right)
$$

where $W_{a y}$ is the mean weight at age from the length-weight relationship model (2.12). The input data are from the results of age-disaggregated dynamic production model.

### 2.2.5 Surplus production model

Here is a model from Polacheck et al. (1993). Now that surplus -production models have moved away from their equilibrium-based origins they provide a useful tool in the assessment of stocks for which there is only limited information available. They also can provide insights as to the relative performance of the stock through time. The available data, biomass indices from survey (Table 4) and CPUE (Table 3) from Danish seine fleets log-books, are used for fitting the surplus -production model. The generalised stock production model is:
$B_{t+1}=B_{t}+\frac{r}{p} B_{t}\left(1-\left(\frac{B_{t}}{K}\right)^{p}\right)-Y_{t}$
where ${ }^{Y_{t}}$ is the total catch in year t , and ${ }^{p}$ is a constant, here assuming $p=1,0.00001$,if $\mathrm{p}=1$, this is equivalent to the Schaefer model, and if $\mathrm{p}=0$, this is equivalent to the Fox model.

The fitting method is as follows:

$$
\begin{aligned}
& S S E B=\sum_{y=1987}^{2004}\left(\ln \left(B_{y}\right)-\ln \left(\hat{B}_{y}\right)\right)^{2} \\
& S S E U=\sum_{y=1991}^{2004}\left(\ln \left(U_{y}\right)-\ln \left(\hat{U}_{y}\right)\right)^{2} \\
& S S E=w_{b} * S S E B+w_{u} * S S E U
\end{aligned}
$$

where $\operatorname{SSE}$ is total sum of squared errors, $B_{y}, U_{y}$ is biomass index from survey and CPUE indices from the logbooks of Danish seine fleets since 1991-2004, $\hat{B}_{y}, \hat{U}_{y}$ is the predicted biomass index and abundance indices from the surplus production model.

The parameters $K, r$ were estimated from the catch by year, biomass index from the survey and CPUE, by finding the best fit to the observed data, and then the biomass at year, surplus production, MSY and instantaneous fishing mortality rate at MSY can be estimated.

### 2.2.6 Biological reference points

In order to define these long term objectives the values of the fishing level have to be considered, which allow loose catches in weight, while also ensuring the conservation of the stocks. The extreme values of the biomass or the fishing level, which might seriously affect the self renovation of the stocks, also have to be considered. These fishing level values, of catch and biomass are designated as biological reference points (BRP) (Emygdio 2003).

For this section's analyses, some models are used to validate the average size-F estimates we obtained earlier, and to assess several biological reference points important to fishery management. The most relevant contemporaneous fishery management benchmarks include: $\mathrm{F}_{0.1}, \mathrm{~F}_{\text {max }}, \mathrm{F}_{\mathrm{msy}}, \mathrm{F}_{\mathrm{med}}, \mathrm{F}_{\text {high }}, \mathrm{F}_{\text {crash }}, \mathrm{B}_{0.1}, \mathrm{~B}_{\text {loss }}, \mathrm{B}_{\mathrm{pa}}$ and $\mathrm{F}_{\mathrm{pa}}$.

- $F_{0.1}$ is the value of $F$ where $Y / R$ is equal to 10 percent of (Y/R) maximum.
- $F_{\text {max }}$ is the point of the curve, $Y / R$ against $F$, where $Y / R$ is maximum.
- $\mathrm{F}_{\mathrm{msy}}$ is the value of F which produces the maximum yield in the long term.
- $\mathrm{F}_{\text {med }}$ is the F value corresponding to the median $\mathrm{B} / \mathrm{R}$ ratio in the long term $\mathrm{B} / \mathrm{R}$ relation against F .
- $\mathrm{F}_{\text {high }}$ is the F value corresponding to the lower $\mathrm{B} / \mathrm{R}$ ratio (fractile is $10 \%$ ) in the long term $B / R$ relation against $F$.
- $\mathrm{F}_{\text {crash }}$ is the fishing level F which will produce a long term spawning biomass per recruit ( $\mathrm{S} / \mathrm{R}$ ) equal to the inverse of the instantaneous rate of variation of R with the biomass.
- $B_{0.1}$ is the spawning biomass value corresponding to the $\mathrm{F}_{0.1}$.
- $\mathrm{B}_{\text {loss }}$ is the smallest spawning biomass observed in the series of annual values of the spawning biomass (Lowest Observed Spawning Stock).
- $B_{p a}$ is between $1.39 \mathrm{~B}_{\text {loss }}$ and $1.64 \mathrm{~B}_{\text {loss }}$.
- $F_{p a}$ is between $0.47 \mathrm{~F}_{\text {crash }}$ and $0.61 \mathrm{~F}_{\text {crash }}$
- The model used are as follows:

$$
\begin{gathered}
\mathrm{Yr}=\frac{Y}{R}=\int_{0}^{\infty} F_{a} * W_{a} e^{-\left(M+a^{*} F_{a}\right)} d a \\
\operatorname{Sr}=\frac{S}{R}=\int_{0}^{\infty} W_{a} * P_{a} * e^{-\left(M+a^{*} F_{a}\right)} d a \\
R=\frac{\alpha^{*} S}{1+S / K} * e^{N\left(0, \sigma^{2}\right)} \\
\operatorname{Se}=K^{*}(\alpha * S r-1) \\
\operatorname{Re}=\alpha^{*} * S e /(1+S e / K) \\
Y e=\operatorname{Re}^{*} Y r
\end{gathered}
$$

$F_{a}$ is the fishing mortality at age, $M$ is the natural mortality, $R$ is the number of recruits, $W_{a}$ is the average weight at age, $P_{a}$ is the maturity rate at age, Yr is yield per recruitment, Sr is biomass per recruitment, and $\mathrm{Se}, \mathrm{Re}$ and Ye is equilibrium biomass, recruitment and yield.

The input data are the calculated results from biological parameters and above models.

### 2.2.7 A long term prediction

2.2.7.1 A long term prediction based on the analysis of $\mathrm{Y} / \mathrm{R}$ and $\mathrm{S} / \mathrm{R}$ with uncertainty

To obtain the best possible utilisation of the plaice stock, a long term prediction for the catch and biomass is necessary (Stefansson G. 1992). Especially when calculation of yield per recruit, spawning stock per recruit and the relationship between recruitment and spawning stock have been completed, it is possible to calculate the total yield potential of the stock with regard to different effort (fishing mortality). But the effects of variable environmental conditions will bring about differences in recruitment in the future (TemaNord FISHERIES 1997), so here the uncertainty factors are taken into account.

The used model is as follows:
$R=\frac{\alpha^{*} S}{1+S / K} * e^{N\left(0, \sigma^{2}\right)}$
$Y=(Y / R)^{*} R$
$S=K^{*}\left(\alpha^{*}(S / R)-1\right)$
where $e^{N\left(0, \sigma^{2}\right)}$ is the variability of lognormal with a $\mu$ of 0 and variance $\sigma^{2}$.
The input data are the parameters value for growth and recruitment-stock relationship.
2.2.7.2 A long term prediction based on the analysis of surplus production with uncertainty

A similar simulation of uncertainty $(\mathrm{CV}=0.25)$ is carried out with surplus production model here. Assuming the catch in the future is respectively 7150 t (corresponding to the mean fishing mortality from 1987-2004), 5700 t (2004). The model used is as follows:

$$
B_{t+1}=B_{t}+\frac{r}{p} B_{t}\left(1-\left(\frac{B_{t}}{K}\right)^{p}\right) * e^{N\left(0, \sigma^{2}\right)}-Y_{t}
$$

The input data are from the results of surplus production model.

## 3 RESULTS

Most fisheries models in this report are quite complex, involving many parameters and nonlinear relationships between the variables. There are usually no analytical solutions or linearising transformations available for the more difficult models. Numerical methods (Dennis and Schnabel 1983) were used when fitting these multi-parameter, non-linear models to data and R (R Development Core Team 2005) was also used for all of the calculations and the plots here.

### 3.1 Biological parameters

Maximum likelihood method was used to estimate parameters of the von Bertalanffy growth equation (Figure 2). The trawl survey data were used because the trawl survey uses small mesh sizes compared to the Danish seine fleet, and should adequately sample younger age classes. The maximum likelihood method also was used to estimate parameters of the lengthweight relationship (Figure 3). Here, the landing data from 1994-2005 (MRI Databases) was used.

The mean weight at age as calculated using the mean length at age from the von Bertalanffy equation and the length weight relationship above. The results are shown in Table 11.

The parameters of the maturity ogive, $a$ and $p_{50}$, are determined by the least squares method fitting estimated-to-observed maturity they are -0.878 and 4.341 respectively (Figure 4).

### 3.2 Estimation of mean catch in number by age by year from length distribution data

The length distributions are highly mixed, the modes in the distribution are far fewer than the number of ages and the overlap between ages is large. Because of that, some difficulties came up in the fitting process resulting in unreasonable values of the mean lengths or standard deviations, although the total squared errors were relatively low.

Therefore, in some cases the mean length at some ages had to be fixed equal to a more reasonable value from the von Berlalanffy equation. Here we fixed all mean lengths and standard deviations. Some initial values are given as proportions per age class and through iteration values that gave better fit were found (Table 12, Figure 5).

### 3.3 Age-based ADAPT model

The estimates of F , recruitment, and stock size are presented in Table 14 and Figure 7. The model estimates the stock size in 1987 at about $50,000 \mathrm{t}$. Then it declines continuously until in 2000 , it is at the lowest level at about $15,000 \mathrm{t}$. However, it increases after that to about $25,000 \mathrm{t}$ in 2005. This trend shows a good fit to the IGFS data. The average annual recruitment is about 29 million juveniles per year. With a few exceptions, this has however declined during this period, reaching the lowest point in 2005. The uncertainty about recruitment estimates is however highest for the most recent years with the VPA method. The recruitment estimates give a reasonably good fit to the recruitment indices from the survey. The estimated fishing mortality is about 0.33 in 1987. It increases after that continuously until
in 1997, it is at the highest level at about 0.781 , and then starts to decline to about 0.21 in 2004. The mean value of F is about 0.5 from 1987 to 2004. The parameters of the $\mathrm{R}-\mathrm{S}$ relationship are $\mathrm{K}=18,797 \mathrm{t}, \alpha=0.00238(\mathrm{R}=0.00238 * \mathrm{SSB} /(1+\mathrm{SSB} / 18797)$ ). But it did not give a very good fit to the CPUE .

### 3.4 Length-based ADAPT model

The age-disaggregated catches in number by year (Table 12) converted from length distributions from landings were used for the cohort analysis, the biomass and recruitment indices from survey and CPUE from landing for the tuning process (Tables 3, 4, 5). The same procedures were used for the projection. The $\bar{F}_{6-12}$ in the last year is estimated as 0.161 , and parameters of the $\mathrm{R}-\mathrm{S}$ relationship are $\mathrm{K}=19,863 \mathrm{t}, \alpha=0.00225$ ( $\left.\mathrm{R}=0.00225^{*} \mathrm{SSB} /(1+\mathrm{SSB} / 19863)\right)$. The estimates of F , recruitment, parameters of the $\mathrm{R}-\mathrm{S}$ relationship and stock size are presented in Table 14 and Figure 8.

### 3.5 Age-disaggregated dynamic production model

The natural mortality was set at $\mathrm{M}=0.15$ as in the previous methods. The Beverton and Holt stock-recruitment relationship (Beverton 1957) was used to project the recruitment of the stock for each year. The selection pattern was taken from the selection pattern used in the age-based ADAPT model. The mean weight at age and maturity at age as in the previous methods (2.12) were used to calculate the exploitable and spawning biomass and predicted yield. Catch in number by age by year of plaice in Icelandic waters 1987-2004 (Table 2), various total abundance indices such as IGFS biomass indices 1987-2004, Danish seine fleet CPUE and recruitment indices (age 2) from IGFS survey (Tables 3, 4, 5) were used to fit the model. The log scale of errors as used to fit recruitment, CPUE indices and IGFS survey biomass indices in order to attain the best fit of the estimated-to-observed. It should be noted that when log-scale is used, the coefficient of variation (CV) of the data can be estimated as:
$C V=\sqrt{\frac{S S E}{n}}$
where $n$ is number of data points. The results show in Table 15.
The production model fits very well with the series of observed catch in number by age by year, IGFS biomass indices. However, the model does not give a good fit with either of the recruitment indices because of the short time series and high variance in the indices, or Danish seine CPUE indices because of short time series (1991-2004) (Figures 9, 10).

The parameters of the Beverton-Holt stock recruitment relationship were estimated as $K=$ $20416 \mathrm{t}, \alpha=0.0027(\mathrm{R}=0.0027 * \mathrm{SSB} /(1+\mathrm{SSB} / 20416))$. The value of $\bar{F}_{6-12}$ in the last year is estimated as 0.253 . The estimates of F , recruitment, parameters of the R-S relationship and stock size are presented in Table 14.

### 3.6 A short term yield and biomass prediction

Population numbers for the catch forecast were taken from the age-based model, the length-
based ADAPT and the production models output and recruitment from the mean value during the period 2002-2004. Fishing mortalities were also the mean F at age in 2004. Although F has shown a general decreasing trend over the last six years (1999-2004), this trend does not appear to have been continued into 2004 for the age-disaggregated dynamic production model and the last year value of F would be used for the prediction. The predicted landings and SSB in 2005-2007 are given in Table 16. The short term predictions show the same declining trend in catch and biomass as age-based ADAPT and the length-based ADAPT models because of under estimates for the recruitment in the last two years, while the slightly increasing trend in catch and biomass is from the production models, and the estimated catch and biomass will increase to around 5,600 t and 26, 000t by 2007.

### 3.7 Surplus production model

The parameters $K, r$, MSY and $F_{M S Y}$ were estimated from the catch by year, biomass index from survey and CPUE, by finding the best fit to the observed data. The model fits very well with the series of observed IGFS biomass. However, the model does not give a good fit with the Danish seine CPUE indices, the predicted results are given in Table 18 and Figures 11-13. The present biomass is estimated at between 21,675 and 19,244 t depending on the $p$ value used (Table 18), other parameters like $\mathrm{K}, \mathrm{r}, \mathrm{MSY}, \mathrm{F}_{\text {msy }}$ and $\mathrm{B}_{\text {msy }}$ respectively are 95,018 $78,883 \mathrm{t}, 0.256-0.477,8,933-9,410 \mathrm{t}, 0.256-0.239$ and 34,955-39,442 t. The analysis of the surplus production model demonstrates that the exploitable stock has been declining from around $90,000 \mathrm{t}$ of unfished biomass in 1905 to the current level of around 20,000 t (Figure 13), because the catch was always more than the surplus production during the periods 19461971 and 1983-1999 after 2000 the catch has been maintained about 5,000 $t$, and the stock has increased slightly to around $21,000 \mathrm{t}$, this is consistent with the survey data.

### 3.8 Biological reference points

All the estimated biological reference point values are given in Table 17 and Figures 14-20. $\mathrm{F}_{\mathrm{pa}}, \mathrm{B}_{\mathrm{pa}}$ were considered according to FAO's recommendation (Emygdio 2003). The rate of fishing mortality that produces "maximum sustainable yield" from Y/R , $\mathrm{F}_{\text {max }}$ was about 0.39. But fishing at Fmax reduced spawning stock biomass and the spawning potential ratio (the proportion of the virgin spawning biomass available) to about $29,502 \mathrm{t}$ and $25 \%$ respectively. At F 0.1 SSB and SSB/B0 was $66,530 \mathrm{t}$ and $55 \%$ (mean SSB/B0) respectively. Remarkably, the current estimated rate of fishing mortality of $\bar{F}=0.5$ for the mean F from 1987-2004 has reduced the SSB, SSB/B0 and recruitment to $21,276 \mathrm{t}$, less than $18 \%$ of SSB/B0 and almost half the maximum recruitment ( 28 millions) (Figures 15-18). In Figures 19-20, the most recent fishing mortality (1997-2004) is well below the Fpa, this could partly explain the increasing SSB in recent years, but the SSB is below the Bpa from 1997 to 2002, and the current SSB is still at a low level near the Bpa.

The results are shown in Table 17. B0 is virgin stock, and the estimate values for B0 from the surplus production and the R-S relationship of the B-H model are around 90,000 t ( $p=0.00001$ ) and 180,185 t respectively.

### 3.9 Long term prediction

### 3.9.1 Long term prediction based on the analysis of YPR and $S P R$ with uncertainty

The stock and recruitment data for the time series are shown in Figure 9. Here the affects of variable environmental conditions will be taken into account as a variance around the mean ( $\mathrm{CV}=0.25$ ). The typical results from one simulation (section 2.2.7.1) then correspond to the effects of certain environmental conditions on the stock and the catch. One simulation thus provides examples of possible developments of stock and catch for a few years into the future. Other simulations correspond to other possibilities for assumptions or environmental conditions. About 100 simulations of a catch and biomass should give a survey of what kind of development is likely and what is unlikely to happen. Here the annual catch used was $7,150 \mathrm{t}$ (corresponding to 0.5 of fishing mortality), 5,700 t (2004) and 4,000 t respectively (MRI recommendation) and then simulated 100 times. The predicted results are given in Table 19 and Figures 21-26. Here the figures display various lines. The narrow lines correspond to a few simulation curves. If all the curves are plotted, the overall picture becomes somewhat unclear. It is, however, possible to plot a line in such a way that for each year one half of the curves is above it and the other half below. This line is represented by the broad. The figures also show $5 \%$ and $95 \%$ fractiles, i.e. those curves that are of such a nature that there is a $5 \%$ or $95 \%$ probability of being above or below them. The broad curve closest to the bottom of the figures thus shows that the probability of stock collapse is less than $5 \%$ since the probability for the spawning stock at each particular time to stay above the lowest curve, which in fact rises with time, is $95 \%$.

The estimates show that the predicted biomass will maintain a stable low level of around $22,000 \mathrm{t}$ until 2020 with $95 \%$ chances of staying between $21,389 \mathrm{t}$ and $27,213 \mathrm{t}$ and $5 \%$ between $21,389 \mathrm{t}$ and $18,861 \mathrm{t}$. The predicted catch also maintains a stable level of $7,200 \mathrm{t}$ with $95 \%$ chances of staying between $7,150 \mathrm{t}$ and $9,155 \mathrm{t}$ and $5 \%$ between $7,150 \mathrm{t}$ and $6,207 \mathrm{t}$, if fishing mortality is 0.5 for each year (mean value from 1987-2004) (Figure 22). For a fishing mortality of 0.38 , the predicted biomass will increase from $21,389 \mathrm{t}$ to $31,313 \mathrm{t}$ with a $95 \%$ probability of changing between $21,389 \mathrm{t}$ and $36,284 \mathrm{t}$ and $5 \%$ probability of changing from $21,389 \mathrm{t}$ to $25,786 \mathrm{t}$. The predicted catch will increase from $5,675 \mathrm{t}$ to $8,537 \mathrm{t}$ with $95 \%$ probability of changing from $5,675 \mathrm{t}$ to $9,824 \mathrm{t}$ and $5 \%$ probability of changing from $5,675 \mathrm{t}$ to $7,019 \mathrm{t}$ (Figure 24). Predicted biomass will increase from $21,389 \mathrm{t}$ to $45,450 \mathrm{t}$ with a $95 \%$ likelihood of changing from $21,389 \mathrm{t}$ to $54,633 \mathrm{t}$ and a $5 \%$ likelihood of changing from $21,389 \mathrm{t}$ to $39,643 \mathrm{t}$. However, the predicted catch at fishing mortality of 0.26 will increase from $4,059 \mathrm{t}$ to $9,026 \mathrm{t}$ with a $95 \%$ likelihood of changing from $4,059 \mathrm{t}$ to $10,895 \mathrm{t}$ and a $5 \%$ likelihood of changing from $4,059 \mathrm{t}$ to $7,845 \mathrm{t}$ (Figure 26).

### 3.9.2 Long term prediction based on the analysis of surplus production with uncertainty

Given annual catch of $5,700 \mathrm{t}$ (2004) and $7,150 \mathrm{t}$ (the mean fishing mortality from 1987 to 2004 is 0.5 ) and then simulated 100 times. The predicted results are given in Table 20 and Figures 27-32. The predictions from the surplus production model also show that the predicted biomass will increase to $61,443 \mathrm{t}$ in 2018 from $23,959 \mathrm{t}$ in 2005 with $95 \%$ chances of staying between 27,962 $t$ and $68,833 \mathrm{t}$ and $5 \%$ between 21,568 t and 53,179 t (Figure 28), the predicted equilibrium yield will decrease from $8,435 \mathrm{t}$ to $6,846 \mathrm{t}$ with $95 \%$ probability of changing from $8,741 \mathrm{t}$ to $7,869 \mathrm{t}$ and $5 \%$ probability of changing from $8,173 \mathrm{t}$ to $5,661 \mathrm{t}$ (Figure 29), if catch for each year is $5,700 \mathrm{t}$. At the same time, if catch for each year is $7,150 \mathrm{t}$ then the predicted biomass will increase from $23,135 \mathrm{t}$ to $48,234 \mathrm{t}$ with $95 \%$ chances of staying between $27,626 \mathrm{t}$ and $57,406 \mathrm{t}$ and $5 \%$ between $20,207 \mathrm{t}$ and $33,984 \mathrm{t}$ (Figure 31). The predicted equilibrium yield will decrease from $8,376 \mathrm{t}$ to $8,505 \mathrm{t}$ with $95 \%$ probability of changing from $8,721 \mathrm{t}$ to $8,919 \mathrm{t}$ and $5 \%$ probability of changing from $7,994 \mathrm{t}$ to $7,387 \mathrm{t}$ (Figure 32).

### 3.10 Comparison of results from models

### 3.10.1 Fishing mortality

The overall pattern in fishing mortality rates ( $\mathrm{F}_{6-12}$ ) as estimated by the three different models show a similar trend (Figure 33). Fishing mortality is relatively low at the beginning of the target fishery in 1987 and then increases until 1999. After 1999, fishing mortality decreases again to a minimum in 2004. The length-based ADAPT model gives somewhat lower Fs at the beginning of the period (1987-1998) and the production model suggests higher Fs in the period. The estimates from the age-based ADAPT model indicates an increase in value of Fs in the first three years and then the Fs decrease again until 1999. All three models give similar estimates for F in the last years, or from 0.16 to 0.25 (for 6-12 years old).

### 3.10.2 Stock size

The age-based model, the production model, the length-based ADAPT model and surplus production model give almost the same trend for stock biomass in the period 1987-2004 (Figure 34). In recent years, the biomass seems to be slowly increasing. The stock is estimated to be around $50,000 \mathrm{t}$ in 1987 and in the range of $22,000-31,000 \mathrm{t}$ in 2004. The production model gives the lowest value, the age-based ADAPT and surplus production models give similar values. The length-based ADAPT model gives lower estimate of the stock biomass (around $41,364 \mathrm{t}$ ) in the beginning but higher ( $31,497 \mathrm{t}$ ) in the last year. This reflects the relatively low F values estimated from this model.

### 3.10.3 Recruitment

The estimates of recruitment (age 2) from the three methods are shown in Figure 35. The trend in the recruitment pattern is similar except for the last two years. While the results from length-based ADAPT and age-based ADAPT models show a similar trend of a sharp decrease in the last two years. The lower values from the age-based ADAPT and lengthbased ADAPT models in the last two years compared to the production model results reflect
the good fit in recruitment indices from the survey in the final year. The production model gives a smooth recruitment pattern with a declining trend over the period.

### 3.10.4 Yield and biomass prediction

### 3.10.4.1 Short term yield and biomass prediction

The results of yield and biomass predictions for the years 2005-2007 from the three models given, after refitting the three models with different assumptions of fishing mortality rates of $\mathrm{F}=0.211,0.161$ and 0.253 are presented in Table 16.

The results from the age-based model and length-based model are very similar for the yield (5,400-4,800 t) and have a gradual decrease because of the lower estimate for recruitment in the last two years, and the biomass prediction from the length-based model is very high (38,000-35,000 t), but the results of the production model are stable (yield: 5,400-5,600 t, biomass: $26,000 \mathrm{t}$ ) and have a slight increase because of its optimistic stock assessment in the last year.

### 3.10.4.2 Long term yield and biomass prediction

Two models for the long term prediction give a similar trend while the prediction values are not the same. For the model based on the analysis of $\mathrm{Y} / \mathrm{R}$ and $\mathrm{S} / \mathrm{R}$, given fishing mortality respectively being 0.5 (mean F from 1987-2004), 0.38 (catch=5,700 t for 2005) and 0.26 (catch $=4,000 \mathrm{t}$ for 2005 from MRI recommendation). The predictions of yield and biomass respectively are around $7,200 \mathrm{t}$ and $22,000 \mathrm{t}, 6,000-85,000 \mathrm{t}$ and 21,000-31,000 $\mathrm{t}, 4,000-9,000$ t and 21,000-45,000 t (Table 19, Figures 21-26). The model based on the analysis of surplus production gives bigger values for the equilibrium yield and biomass $8,500 \mathrm{t}$ and 23,000 $48,000 \mathrm{t}$ for the catch $7,150 \mathrm{t}, 8,500-7,000 \mathrm{t}$ and $24,000-60,000 \mathrm{t}$ for the catch 5,700 t (Table 20, Figures 27-32), because in the condition of same biomass, the surplus production model will give bigger equilibrium yields.

## 4 DISCUSSION AND FUTURE WORK

All models, as well as the survey index and CPUE from fishing fleets, indicate that the plaice stock biomass is at a low level close to Bpa, though current biomass is increasing slowly. Taking these estimates into account, if catch is carried out according to Table 19, the long term yield and biomass are probably at a level of around $9,000 \mathrm{t} / \mathrm{y}$ and $40,000 \mathrm{t}$. It has to be considered however that the assessment for this stock can overestimate SSB and underestimate fishing mortality because discard estimates are not included in the assessment.

The age-based ADAPT method gave lower recruitment like the length-based method in the last two years. The most likely explanation is that recruitment indices are declining rapidly in recent years from the survey (Table 5, 21-25 cm). The uncertainty in recruitment estimates is however high for at least two reasons: firstly because uncertainty about the recruitment for the last years is inherited in the VPA method and secondly is because the recruitment indices from the survey can be inaccurate since they are based on length frequency data.

The length-based method gave the most optimistic estimate of stock size and recruitment in the last two years is also low like in the age-based ADAPT model. This is probably because it was based on rather uncertain catch in number at age. The large number of age groups and slow growth of plaice gives serious problems when disaggregating the length distributions. Future work should emphasise parameter reduction techniques such as fixing all mean lengths at age across years or incorporating the length distributions directly as data into the age-disaggregated production model.

The production model gave a very good fit for the catch in number by age by year and biomass indices from survey. It could account for the recent recruitment events, which are reflected in the results of the other models, such as the surplus production model. In the future, one can expand the fitting process of the age-disaggregated production model by using weights on index series and trying to do the bootstrap to test different error scales (logtransform or normal) and confidence intervals.

The predicted yield for the years 2005-2007 is consistent between the three models (4,800$5,600 \mathrm{t}$ ), but the length-based ADAPT model gives higher estimates of stock size.

The surplus production model demonstrates that stock size of plaice changed and why stock size had been decreasing rapidly from 1905-2004, but the data for model fit are only from 1987-2004. This may produce errors to the estimation of K and $\alpha$ for the model.

The estimates for biological reference points are based on the von Bertalanffy equation, length-weight relationship, maturity proportion, natural mortality, selection pattern and R-S relationship, the errors for each part estimated above may lead to errors in biological reference points. At same time, the MSY is similar to the surplus production model, according to the analysis of biological reference points, in the long run, these reference points are important for plaice fisheries management.

One hundred simulations of two models for long term prediction with uncertainty ( $\mathrm{CV}=25 \%$ ) gave approximately the same results of yield, but gave different values of biomass prediction
with an optimistic estimate for the surplus production model. The two models predict that the current very low biomass will increase to $30,000 \mathrm{t}$ in five years for the prediction based on the analysis of $\mathrm{Y} / \mathrm{R}$ and $\mathrm{S} / \mathrm{R}$ and $36,000 \mathrm{t}$ for the prediction based on the surplus production model. If catches are kept at a constant level of $4,000 \mathrm{t} / \mathrm{y}$ and $5,700 \mathrm{t} / \mathrm{y}$ for the surplus production model, or the fishing mortality constant at 0.26 and 0.38 for the surplus production model, then the stock size will increase to $41,000 \mathrm{t}$ and $55,000 \mathrm{t}$ respectively by 2015.. At the same time, the sustainable yield will increase to about $8,000-9,000 \mathrm{t}$ and 7,000 $-8,500 \mathrm{t}$. The current very low biomass will be maintained by 2020 for the model based on analysis of $Y / R$ and $S / R$ if the fishing mortality is kept at a constant level of mean fishing mortality in $1987-2004$, or $\mathrm{F}=0.5$.

The plaice is mostly fished in the North Sea and close by waters. The stocks are in various shapes, some such as in the Irish Sea are increasing and in good health (mostly based on catch at age models www.ices.dk). The North Sea stock itself is however at a current low level, or below Bpa.

China, like Iceland, is endowed with substantial fish stocks in both its inshore and offshore waters. The stock sizes have not yet been sufficiently studied. The plaice which is fished in Icelandic waters differs in many respects from the fishes of China, but some of the methods and skills used to develop this project may be applicable to Chinese conditions. At the same time, these methods and skills must benefit the marine fisheries education of China in the future.

## 5 CONCLUSION

- Fishing mortality has declined to historical lows since 1987. The fishing mortality estimated in 2004 of 0.25 is however well below the Fpa of 0.6 (Figure 20). It is interesting to note that our Fpa is the same value as for North Sea plaice (www.ices.dk).
- Recruitment between 1987 and 2004 was variable and included few high values. Since 2000, recruitment has been less than average ( 30 millions) (Table 14).
- The SSB estimated in 2004 of around $22,000 \mathrm{t}$ is above the $\mathrm{B}_{\mathrm{pa}}$ of around $15,000 \mathrm{t}$. SSB was relatively low in the 1990s, while SSB has a slightly increasing trend if the fishing mortality maintains the current levels for the future (Figure 20).
- The estimates from the two long term predictions show that the probability of the SSB falling below $\mathrm{B}_{\mathrm{pa}}$ remains very small, even if fishing mortality is 0.5 (Figures 21-32).
- The predictions from the reference points model show that current $\mathrm{F}(0.25)$ is close to the value ( 0.2 ) giving maximum yield (Figures 16-18).
- For the increasing SSB to around $40,000 \mathrm{t}$ as quickly as possible, fishing mortality from 2005-2014 should be maintained below 0.26 (Figure 26).

## ACKNOWLEGMENTS

I am very grateful to my supervisor Mr. Hreiðar Pór Valtýsson for his excellent guidance and support during the course of my project. I would like to thank members of the Marine Research Institute and Akureyri University who gave me direct and indirect support for my work.

Great thanks and appreciation to Dr. Tumi Tómasson, Director of the UNU Fisheries Training Programme and Mr. Pór Ásgeirsson, Deputy Director of the programme for encouragement and support during my studying here.
